Abstract. Biomass burning emits an estimated 25 % of global annual nitrogen oxides (NO_x), an important constituent that participates in the oxidative chemistry of the atmosphere. Estimates of NO_x emission factors, representing the amount of NO_x per mass burned, are primarily based on field or laboratory case studies, but the sporadic and transient nature of wildfires makes it challenging to verify whether these case studies represent the behavior of the global fires that occur on earth. Satellite remote sensing provides a unique view of the earth, allowing for the study of emissions and downwind evolution of NO_x from a large number of fires. We describe direct estimates of NO_x emissions and lifetimes for fires using an exponentially modified Gaussian analysis of daily TROPospheric Monitoring Instrument (TROPOMI) retrievals of NO_2 tropospheric columns. We update the a priori profile of NO_2 with a fine-resolution (0.25°) global model simulation from NASA's GEOS Composition Forecasting System (GEOS-CF), which largely enhances NO_2 columns over fire plumes. We derive representative NO_x emission factors for six fuel types globally by linking TROPOMI-derived NO_x emissions with observations of fire radiative power from Moderate Resolution Imaging Spectroradiometer (MODIS). Satellite-derived NO_x emission factors are largely consistent with those derived from in situ measurements. We observe decreasing NO_x lifetime with fire emissions, which we infer is due to the increase in both NO_x abundance and hydroxyl radical production. Our findings suggest promise for applying space-based observations to track the emissions and chemical evolution of reactive nitrogen from wildfires.

1 Introduction

Biomass burning emissions affect global radiative forcing, the hydrological cycle, the ecosystem, and air quality (e.g., Crutzen and Andreae, 1990; Penner et al., 1992; Johnston et al., 2012; Liu et al., 2014). Biomass burning emits an estimated 25 % of global annual nitrogen oxides ($\text{NO}_x = \text{NO} + \text{NO}_2$), an important constituent that participates in the oxidative chemistry of the atmosphere, leading to the formation of tropospheric ozone (O_3) and secondary aerosols that affect air quality, ecosystem, health and climate. Unlike other NO_x sources such as power plants that are persistent and relatively static, the sporadic and transient nature of wildfires makes it challenging to estimate emissions experimentally over wide spatial and temporal scales (Ichoku and Ellison, 2014). Biomass burning emissions inventories used in models are subject to uncertainties in estimates or measurements of the burned area, fuel loadings, combustion efficiency and also the compound-specific emission factors that relate the mass of a chemical species emitted to fuel consumption (e.g., Petrenko et al., 2012; Liu et al., 2020; Carter et al., 2020). Current estimates of NO_x emission factors are primarily based on field measurements that sample a few fires over a small region (Yokelson et al., 2007; Alvarado et al., 2010; Lindaas et al., 2021) or laboratory studies that measure fire emissions under controlled conditions (McMeeking et al., 2009; Roberts et al., 2020). These previous studies report large variations of NO_x emission factors, even in a similar ecosystem, which could be due to variation in individual fire conditions, nitrogen content of the fuel burned, or differences in sampling techniques and analysis methods (Andreae, 2019). The NO_x emission factors used in global

biomass burning emission inventories also vary (Wiedinmyer et al., 2011; Kaiser et al., 2012; Darmenov and Silva, 2015; van der Werf et al., 2017). These varying perspectives raise the question of how well we understand how to extrapolate the emission factors derived from individual fires to the large number of fires that occur annually on the globe, each with distinct fire conditions, intensity, and fuel type.

Satellite remote sensing provides a unique view of the earth, which offers the opportunity to study a large number of fires globally. Satellite-based products such as fire radiative power (FRP) and burned area have been widely used in the fire detection (Wiedinmyer et al., 2011; van der Werf et al., 2017). The launch of GOME-1 in 1995 set the milestone for monitoring NO_x from space (Richter et al., 2005). The Ozone Monitoring Instrument (OMI) aboard the Aura satellite has a finer spatial resolution with $13 \times 24 \text{ km}^2$ at nadir, which is widely used to detect NO_x emissions from anthropogenic sources (Beirle et al., 2011; Lu et al., 2015; Duncan et al., 2016; Liu et al., 2016). These studies typically rely on aggregation of multiple observations to reduce the noise of satellite retrievals or improve spatial resolutions via oversampling, tools which cannot be used to study the rapidly varying NO_x from fires. In October 2017, the Tropospheric Monitoring Instrument (TROPOMI) launched to space (Veefkind et al., 2012). The finer spatial resolution ($\sim 7 \times 3.5 \text{ km}^2$) and the improved signal-to-noise ratio of TROPOMI compared to OMI offer new opportunities to more reliably interpret observations of individual plumes (Veefkind et al., 2012; Judd et al., 2019; van Geffen et al., 2020).

The accuracy of satellite retrieval of NO₂ columns largely depends on the a priori knowledge of NO₂ vertical profile shape needed for calculating air mass factor (AMF) (e.g., Boersma et al., 2018; Verhoelst et al., 2021). The impacts of the a priori profile are especially evident for fire plumes with intense emissions and varying plume dynamics (Bousserez, 2014). Previous studies that use satellite observations to derive NO_x emission factors (EFs) from fires all show lower EFs than in situ measurements, which could be due to inaccurate a priori profiles (Mebust et al., 2011; Mebust and Cohen, 2014; Schreier et al., 2015). Replacing the a priori vertical profile from a fine-resolution regional model can enhance the spatial gradient and correct the low bias of satellite-retrieved NO₂ over polluted regions (e.g., Russell et al., 2011; Valin et al., 2011; Goldberg et al., 2017; Ialongo et al., 2020; Judd et al., 2020; Tack et al., 2021). However, conducting fine-resolution simulations for fires distributed globally is currently too computationally expensive for routine analysis. The GEOS Composition Forecasting System (GEOS-CF) produced by NASA Global Modeling and Assimilation Office (GMAO) provides real-time global simulations of atmospheric composition at a fine resolution of 0.25° (Keller et al., 2021). The GEOS-CF has provided an opportunity for capturing fine-scale features relevant to biomass burning plumes. Here we apply GEOS-CF NO₂ as the a priori profile to recalculate AMFs for TROPOMI NO₂ columns near fires, and

we show that updating the a priori profile could resolve the underestimate of satellite-based NO_x emission factors suggested in previous studies (Mebust et al., 2011; Mebust and Cohen, 2014; Schreier et al., 2015).

Satellite instruments observe fire NO_x plumes as a mixture of fresh and aged smoke. NO_x is a short-lived species, and its concentration will decay in the plume due to the formation of nitric acid (HNO₃), peroxyacetyl nitrate (PAN), and organic nitrates (RONO₂). The relationship between satellite-observed NO_x concentration and emissions depends on the loss rate of NO_x. The chemical processes governing the lifetime of NO_x in the fire plumes are poorly understood (Alvarado et al., 2010). Previous studies assume a constant chemical NO_x lifetime of 2 h (Mebust et al., 2011; Mebust and Cohen, 2014). Laughner and Cohen (2019) provide space-based evidence of changing NO_x lifetimes over US cities as NO_x emissions decline. As fire intensity varies by several orders of magnitude, assuming constant NO_x lifetime for all fires will likely introduce errors in the derived NO_x emissions (De Foy et al., 2014). The improved spatial resolution of TROPOMI allows for direct measurements of the length scale of NO₂ decay. By analyzing the plume evolution downwind, we derive an effective NO_x lifetime. Beirle et al. (2011) first proposed an exponentially modified Gaussian (EMG) approach to directly estimate NO_x emissions and lifetimes from satellite observations, which has been widely used to derive NO_x emissions from anthropogenic sources (Beirle et al., 2011; Lu et al., 2015; Goldberg et al., 2019; Laughner and Cohen, 2019). Our study is the first to apply the EMG approach to simultaneously estimate NO_x emissions and lifetimes from biomass burning plumes. The resulting emission estimates provide a large ensemble with which to evaluate current emission models and also provide detailed constraints on the chemical evolution of NO_x. The resulting lifetimes provide insights into hydroxyl radical abundances in the plume and thus constraints on the lifetime of other chemicals emitted from fires.

2 Datasets

TROPOMI is a nadir-viewing hyperspectral spectrometer launched on 13 October 2017 by the European Space Agency (ESA) for the European Union's Copernicus Sentinel-5 Precursor (S5P) satellite mission. TROPOMI provides afternoon ($\sim 13:30 \text{ LT}$, local time) global observations in UV–visible–near-infrared spectra with a fine spatial resolution of $7 \times 3.5 \text{ km}^2$ at nadir (increased to $5.5 \times 3.5 \text{ km}^2$ since August 2019). We obtain the daily level-2 TROPOMI retrievals of NO₂ tropospheric column density data from April 2018 to June 2020 from NASA Goddard Earth Sciences (GES) Data and Information Services Center (DISC) (Copernicus Sentinel-5P, 2018a). The retrieval of the NO₂ tropospheric vertical column includes three steps (van Geffen et al., 2019): (1) retrieval of the total slant column density along the op-

tical path using differential optical absorption spectroscopy (Boersma et al., 2011); (2) subtraction of the total slant column density from stratospheric NO₂ slant column based on information from a data assimilation system (Boersma et al., 2018); and (3) conversion of the tropospheric slant column density to vertical column density using AMFs, which are obtained from radiative transfer calculations that account for the viewing geometry, cloud fraction, surface properties, and the a priori vertical profile of NO₂ (Boersma et al., 2018). We include TROPOMI observations with the quality assurance value higher than 0.5, which filters out problematic retrievals but still keeps good quality retrievals over cloud (or aerosols). In addition to NO₂, we obtain TROPOMI aerosol layer height (ALH) or aerosol layer pressure (ALP) data, which provide height information of aerosol layer in the troposphere (Copernicus Sentinel-5P, 2018b). Retrieval of ALH or ALP is based on the O₂ absorption band at near-infrared wavelengths between 759 and 770 nm (Graaf et al., 2019). Details of the aerosol layer retrieval algorithms can be found in Graaf et al. (2019) and Nanda et al. (2019).

We use the Moderate Resolution Imaging Spectroradiometer (MODIS) Active Fire products (collection 6) to provide information on the intensity and location of fires (Giglio et al., 2016), which are available from NASA's Fire Information for Resource Management System (NASA FIRMS, 2018a). We include daytime MODIS measurements from the Aqua satellite to match with the overpass of TROPOMI. Fire detection from MODIS is performed using a contextual algorithm that measures the infrared radiation from fires (Giglio et al., 2016). Each hotspot is recorded as the center of an $\sim 1 \times 1$ km² pixel that contains one or more fires, and the FRP is estimated via an empirical relationship using the 4 μ m band brightness temperatures (Kaufman et al., 1998). We group fire pixels whose distances are within 20 km as a single fire event, and the center of the fire is calculated as the mean of fire pixel locations weighted by pixel FRP. To assess the sensitivity to the choice of FRP product, we also process the daytime Suomi NPP Visible Infrared Imaging Radiometer Suite (VIIRS) observations of active fire data (NASA FIRMS, 2018b). The VIIRS fire product uses a similar algorithm as MODIS for fire detection (Schroeder et al., 2014). To assess potential effects of aerosol from plumes on satellite retrieval of NO₂, we acquire the Multi-Angle Implementation of Atmospheric Correction (MAIAC) aerosol optical depth (AOD) level-2 1 km daily gridded product (MCD19A2) from NASA's Earth Observing System Data and Information System (EOSDIS). Details of the retrieval of AOD can be found in Lyapustin et al. (2012, 2018a, b).

The fire episodes are classified based on MODIS-detected fire location following the fuel classification in the Global Fire Emission Database (GFED), which is estimated using the MODIS land cover type product and University of Maryland classification scheme (Friedl et al., 2010; van der Werf et al., 2017). We assign the fuel type to grid cells with mixed fuel types based on the dominant fuel type. We follow the

definition of GFED, grouping savanna, grassland, and shrubland fires as a single herbaceous fuel type. To assess if the NO_x EF varies among these three herbaceous types, we use the 500 m yearly MODIS land cover product (v5) to classify the herbaceous fires based on the dominant land cover type (Friedl et al., 2010). We use wind fields from the hourly ERA-5 reanalysis data developed by the European Centre for Medium-Range Weather Forecasts (ECMWF), which provides meteorological variables at $0.25^\circ \times 0.25^\circ$ resolution with 37 pressure levels from 1000 to 1 hPa from 1979 to present (Hersbach et al., 2018, 2020). We sample ERA-5 wind data closest to the center of each fire episode at the TROPOMI overpass time ($\sim 13:00$ LT).

3 Methods

3.1 An improved fire a priori profile for TROPOMI NO₂

The a priori vertical profiles of NO₂ used in the standard TROPOMI products are obtained from global daily model simulations (TM5) with coarse resolution (1°) and monthly average biomass burning emissions (Williams et al., 2017). Fires are intrinsically episodic and occur over land areas that are often as small as a few kilometers. Here we recompute the tropospheric AMFs using the vertical NO₂ profiles provided by the NASA GEOS-CF simulations with 0.25° resolution. The GEOS-CF system combines the GEOS weather analysis and forecasting system with GEOS-Chem chemistry scheme version 12.0.1 (Bey et al., 2001; Keller et al., 2014, 2021; Long et al., 2015). GEOS-CF includes detailed gas-phase and aerosol chemistry (Knowland et al., 2020; NASA GMAO, 2020; Keller et al., 2021). The near-real-time satellite-based Quick Fire Emission Database (QFED v2.5) is used to provide daily biomass burning emissions (Darmenov and Silva, 2015). In the GEOS-CF system, 65 % of biomass burning emissions are distributed within the boundary layer, and the other 35 % are distributed evenly between 3.5 and 5.5 km (Fischer et al., 2014). GEOS-CF provides hourly global vertical profiles of NO₂ at 23 pressure levels from 1000 to 10 hPa since 2018.

We sample GEOS-CF products at the time and location of all fire episodes identified. For each episode, we spatially interpolate the NO₂ profiles simulated by GEOS-CF to match the resolution of TROPOMI products. The AMF (AMF_{GC,clear}) for clear sky conditions can be calculated following Eq. (1):

$$\text{AMF}_{\text{GC,clear}} = \frac{\sum_{\text{surf}}^{\text{trop}} m_l \times x_{\text{GC},l}}{\sum_{\text{surf}}^{\text{trop}} x_{\text{GC},l}}, \quad (1)$$

where m_l is scattering weight, which is a function of satellite-viewing geometry, surface pressure, reflectivity, etc.; $x_{\text{GC},l}$ is

the GEOS-CF subcolumn for layer l . We acquire averaging kernels (AKs) from TROPOMI level-2 products, and we interpolate GEOS-CF vertical profiles to the 34 vertical layers that provide information on AKs. AK is equal to the ratio of the scattering weight to the tropospheric AMFs computed from the a priori profile (AMF_a) (Eskes and Boersma, 2003):

$$AK_l = \frac{m_l}{AMF_a}. \quad (2)$$

Combining Eq. (1) and Eq. (2) gives Eq. (3):

$$AMF_{GC,clear} = \frac{AMF_a \times \sum_{surf}^{trop} AK_l \times x_{GC,l}}{\sum_{surf}^{trop} x_{GC,l}}. \quad (3)$$

Given that AMF_a is the ratio of slant columns to vertical columns, we can relate the vertical columns with GEOS-CF-simulated profile ($\Omega_{GC,clear}$) to the originally retrieved vertical columns (Ω_a) as Eq. (4):

$$\Omega_{GC,clear} = \Omega_a \times \frac{\sum_{surf}^{trop} x_{GC,l}}{\sum_{surf}^{trop} AK_l \times x_{GC,l}}. \quad (4)$$

For partly cloudy scenes, the air mass factor can be written as a linear combination of a clear and cloudy AMF as in Eq. (5) (Boersma et al., 2004):

$$AMF_{GC} = f_{cloud} AMF_{GC,cloud} + (1 - f_{cloud}) AMF_{GC,clear}, \quad (5)$$

where f_{cloud} is radiance-weighted cloud fraction, and $AMF_{GC,cloud}$ is essentially the above-cloud component of Eq. (3) (Laughner et al., 2018). Therefore, we revise Eq. (4) for the partly cloudy scene as Eq. (6):

$$\Omega_{GC} = \Omega_a \times \left[(1 - f_{cloud}) \frac{\sum_{surf}^{trop} x_{GC,l}}{\sum_{surf}^{trop} AK_l \times x_{GC,l}} + f_{cloud} \frac{\sum_{cloud}^{trop} x_{GC,l}}{\sum_{cloud}^{trop} AK_l \times x_{GC,l}} \right]. \quad (6)$$

3.2 Estimation of emissions and lifetimes of wildfires

We apply an EMG approach to estimate NO_x emissions and lifetime from each fire episode. For each fire episode, we first rotate TROPOMI NO₂ swath data along the wind direction in the range of 200 km around the fire center, and we map the rotated TROPOMI NO₂ column to a regular grid with 0.05° resolution by calculating area-weighted average as described in Jin et al. (2020). Next, we integrate the TROPOMI NO₂ columns in the across-wind direction within ±100 km, which

gives reduced one-dimensional line densities. The NO₂ line densities (L) are then fitted with an EMG model, which is a convolution of a Gaussian-shaped emission and an exponential decay function (Beirle et al., 2011; Lu et al., 2015; Laughner and Cohen, 2019) following Eq. (7):

$$L(x|a, x_0, \mu_x, \sigma_x, B) = \frac{a}{x_0} \exp\left(\frac{\mu_x}{x_0} + \frac{\sigma_x^2}{2x_0^2} - \frac{x}{x_0}\right) \phi\left(\frac{x - \mu_x}{\sigma_x} - \frac{\sigma_x}{x_0}\right) + B, \quad (7)$$

where x_0 is the e -folding distance that represents the length scale of the NO₂ decay, μ_x is the location of the apparent source relative to the fire center, σ_x represents the Gaussian smoothing length scale, ϕ is a cumulative distribution function, a is a scale factor that represents the observed total number of NO₂ molecules in the fire plumes, and B represents the background NO₂. We use the best guesses for initial values following Laughner and Cohen (2019). The effective NO₂ lifetime (τ_{EMG}) and the estimated NO_x emissions (E_{EMG}) can be calculated from the fitted x_0 and a following Eqs. (8) and (9):

$$\tau_{EMG} = \frac{x_0}{w}, \quad (8)$$

$$E_{EMG} = \gamma \times \frac{a}{\tau_{EMG}}, \quad (9)$$

where w is the wind speed, and γ is the ratio of NO_x to NO₂. The effective lifetime should represent chemical lifetime of NO_x if the transport speed is uniform, the direction is constant, and deposition is negligible (De Foy et al., 2014). Previous studies either use the averaged wind of the first several layers (Beirle et al., 2011; Lu et al., 2015) or choose a constant layer such as 900 hPa (Mebust et al., 2011), but injection height of wildfires varies significantly, especially for large fires which inject emissions into high altitudes (Val Martin et al., 2010). To account for varying injection height, we use TROPOMI ALH as an approximation of the fire injection height instead of assuming a constant layer. We vertically interpolate ERA-5 wind data to the pressure level of aerosol layer. For the fires without valid ALH (~36 % of the selected fires), we use 900 hPa, as the ALP level for the majority of selected fires is near 900 hPa (see Sect. 4.1). γ is assumed to be 1.32, which is between the measured mean NO_x/NO₂ ratio of 1.50 reported in Akagi et al. (2012) and 1.24 in Juncosa Clahorrano et al. (2021). We assume a constant γ , because O₃ and the photolysis rate of NO₂ vary little in the plume, and the timescale for NO and NO₂ to reach steady state is on the order of 100 s (Alvarado and Prinn, 2009). Juncosa Clahorrano et al. (2021) show the NO_x/NO₂ ranges from 1.15 to 1.50 near the fire center before 15:00 LT, but the median NO_x/NO₂ varies little from center to plume edge. Mebust et al. (2011) suggest the uncertainty of NO_x/NO₂ is ~20 %.

3.3 Idealized plume model

To understand the factors that control the NO_x lifetime, we employ a one-dimensional (1-D) multi-box plume model based on the Python Editable Chemical Atmospheric Numerical Solver (PECANS; Laughner 2019; Laughner and Cohen, 2019). PECANS is a flexible idealized atmospheric chemistry modeling framework that allows for one box to three-dimensional multi-box simulations of atmospheric chemistry with idealized transport. In this study, we set the model to be 1-D with 600 km domain size and 2.5 km resolution, which is analogous to the integrated 1-D NO₂ line density along wind direction. The wind speed is fixed at 5 m s⁻¹, and the diffusion coefficients are also fixed at 100 m² s⁻¹ following Laughner and Cohen (2019). We assume a simplified set of reactions to represent a chemical condition within the NO_x plume including (1) the permanent removal of NO_x through the formation of HNO₃ and RONO₂, (2) the temporary removal and releases of NO_x by PAN, (3) the instantaneous steady-state relationship between NO and NO_x, and (4) the transport of NO_x along the wind direction. The modeled volatile organic compounds (VOCs) are lumped into two groups: the first group (hereafter RVOC) does not contribute PAN formation, and the second group is modeled as an immediate PAN precursor (hereafter OVOC), specifically acetaldehyde. We include a Gaussian-shaped NO_x emission source (expressed in NO) at $x = 200$ km with 6 km in half width. The concentrations for O₃, hydroxyl radical production rate $P(\text{HO}_x)$, VOC reactivities, and alkyl nitrate branching ratio are given as model input. The O₃ concentration is fixed at 65 ppbv, which is close to observed mean O₃ concentration near fire plumes (Alvarado and Prinn, 2009; Alvarado et al., 2014). A fixed branching ratio of 0.05 to form RONO₂ in the RO₂+NO reaction is used following Laughner and Cohen (2019). We run PECANS repeatedly with varying NO_x emissions, $P(\text{HO}_x)$, RVOC, and OVOC. Each model run outputs the concentration of NO_x and its major sinks along the wind direction, which are then used to calculate both EMG-fitted and chemical NO_x lifetimes.

3.4 Selection of fires

Since not all fire plumes are detectable from space and the EMG approach works best for single sources with clear plume patterns, we apply the following four criteria to select candidate fires from fire plumes identified from MODIS FRP observations (see Fig. S1 in the Supplement for a flowchart of the selection procedure):

First, fires should be large enough so that an apparent enhancement of NO₂ is observed from TROPOMI. Considering the detection limit of TROPOMI NO₂ and the greater uncertainty of MODIS FRP for small fires (Kaufman et al., 1998), fire episodes with MODIS FRP higher than 200 MW are selected. We then select fires where TROPOMI NO₂ tropospheric columns on the fire day are at least 1 standard de-

viation higher than the mean TROPOMI NO₂ columns 30 d before and after the fire day (excluding the nearest 4 d as fires may last for several days, defined as $\Omega_{\text{NO}_2\text{-B}}$). We only include fires in which TROPOMI NO₂ line densities peak near the fire center, meaning that fires with monotonically increasing or decreasing line densities within the region are excluded.

Second, nearby fire plumes should not contribute to the NO₂ line density of the selected fires. A major challenge of applying the EMG approach is that it only applies to a single source, but isolated wildfires are rare in nature. To reduce the influence of nearby plumes, we develop an algorithm that automatically detects and filters out the surrounding plumes (Fig. S2). We first identify plume-affected grid cells defined as Ω_{NO_2} higher than background NO₂ ($\Omega_{\text{NO}_2\text{-B}}$, Fig. S2b). Next, pixels are grouped to separate plumes based on their connections with surrounding pixels, assuming that plume pixels belonging to the same fire event should be connected. We then exclude the plumes that do not belong to the center fire plumes (Fig. S2c). The filtered areas are filled with background $\Omega_{\text{NO}_2\text{-B}}$ (Fig. S2d). The ability of clustering depends on the choice of $\Omega_{\text{NO}_2\text{-B}}$: high $\Omega_{\text{NO}_2\text{-B}}$ may truncate plumes as edges are counted as background, while low $\Omega_{\text{NO}_2\text{-B}}$ may lead to the background being counted as fire plumes, so nearby plumes are connected with center plumes. To optimize the performance, we repeat the clustering and filtering steps with different $\Omega_{\text{NO}_2\text{-B}}$ values, and we select the $\Omega_{\text{NO}_2\text{-B}}$ that maximizes the filtered size of nearby plumes while retains the center plume. This filtering algorithm, however, does not apply to the case where fire plumes are overlapped. Therefore, we further exclude the fire plumes where comparable or larger fires are detected (i.e., total FRP of the nearby plumes is greater than one-third of the selected fire) over the region after applying the filtering.

Third, the fire plumes should align with the wind direction. We define a rotation bias as the angle between the wind direction and the observed apparent plume direction. From previous step, we obtain an approximate region of fire plumes, whose coordinates in x and y directions can be fitted with a line using linear regression, where the slope of the line can be converted to degrees (Fig. S3). We only select fire episodes with rotation biases between -30 and 30° .

Fourth, the fire plumes should give good fitting statistics that satisfy the following criteria: (1) $R^2 > 0.5$; (2) $\sigma_x < x_0$, meaning that emission width is smaller than the e -folding distance, which could prevent the case in which emission shape confounds with lifetime; and (3) $|\mu_x| < 50$ km, meaning that the apparent source center is not too far from the fire center. Fires with more than 50 % missing TROPOMI NO₂ values are excluded. The outcome of the EMG function is sensitive to the initial condition of each fitting parameter. To test the sensitivity of the fitting results to initial conditions, we repeat the fitting with varying initial values for each parameter 50 times, and we exclude fires where the standard deviation of resulting emissions is more than 50 % of the

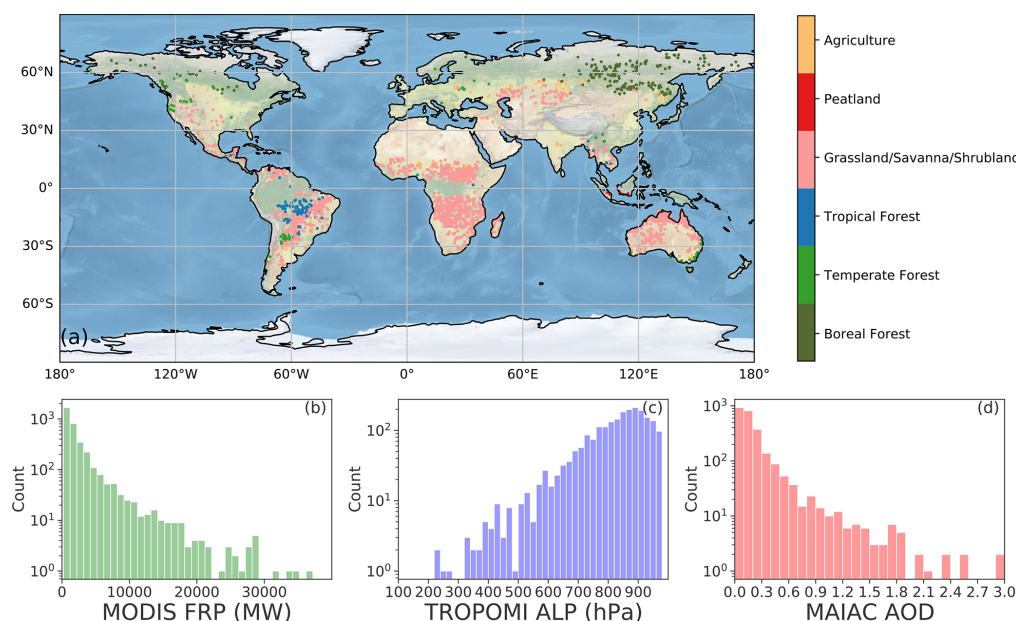

Figure 1. (a) Map of the distribution of selected fire events and corresponding fuel type. Histograms of the distribution of (b) MODIS FRP, (c) TROPOMI ALP, (d) MAIAC AOD for the selected fire events. The number of fire events (y axis) is on a log scale.

emissions. After excluding the fires sensitive to initial conditions, the uncertainty of the emission due to initial conditions is $\sim 5\%$.

4 Results

4.1 Characteristics of selected fires

Applying the above selection criteria, we identified 3248 fire episodes globally between April 2018 and June 2020 suitable for the EMG approach (Fig. 1a). The majority of the fires (77 %) occur in the savanna, grassland, and shrubland ecosystems. We identified 573 (18 %) forest fires, including 227 over the boreal forest, 153 over temperate forest, and 193 over the tropical forest fires. Twenty fire episodes are classified as peatland, which occurred in equatorial Asia. We also identified 158 fires (5 %) due to agriculture waste burning distributed across different regions. Figure 1b to d show the distributions of MODIS FRP, TROPOMI ALP, and MAIAC AOD of the selected fire episodes. The MODIS FRP is below 10 000 MW for 95 % of the selected fires, and 34 fires have FRP larger than 20 000 MW. The mean TROPOMI ALP is 828 hPa (or 1836 m for ALH), with 1σ standard deviation being 118 hPa (or 1751 m). Assuming TROPOMI ALH is indicative of fire injection height, more than 80 % of selected fires inject fire emissions to a pressure level between 700 and 950 hPa. About 83 % of the fire episodes show MAIAC AOD less than 0.3 near the fire center, and only 64 (3 %) fire episodes have AOD higher than 1.0. In summary, most of

our selected fires can be characterized as median to large fires with relatively low injection height and small AOD.

4.2 Emission and lifetime estimates with an example fire

We estimate emissions and lifetime for each selected fire episode. As an example, Fig. 2 illustrates four major steps to estimate NO_x emissions with a fire event occurred in western Australia (27.98°S , 125.90°E) on 21 October 2018. Several NO_2 plumes are detected by TROPOMI on this day, which outperforms OMI observation on the same day which detects less smaller fires, shows less spatial gradients, and larger data gap (Fig. S4). For the fire event selected, we first rotate TROPOMI observations along wind direction (Fig. 2a). Second, we update the a priori profile of NO_2 to improve the estimate of NO_2 column (Sect. 3.1), which leads to an enhancement of NO_2 gradient near the fire center (Fig. 2b). Third, we filter two nearby fire plumes, and the nearby plumes are filled with background NO_2 (Fig. 2c). Fourth, we integrate across the wind direction to obtain a 1-D line density and fit with the EMG function (Fig. 2d and Eqs. 7 to 9). The EMG model captures the variation of the line density ($R^2 = 0.98$). The lifetime is estimated to be 1.6 h, and the total NO_x emissions are estimated as 7870 g s^{-1} .

4.3 Satellite-derived fire NO_x emissions

Deriving NO_x emissions for the large ensemble of fires, we investigate what drives the variation of NO_x emissions and lifetimes among these fires. MODIS FRP, which represents the radiant energy released by fires, has been used to approx-

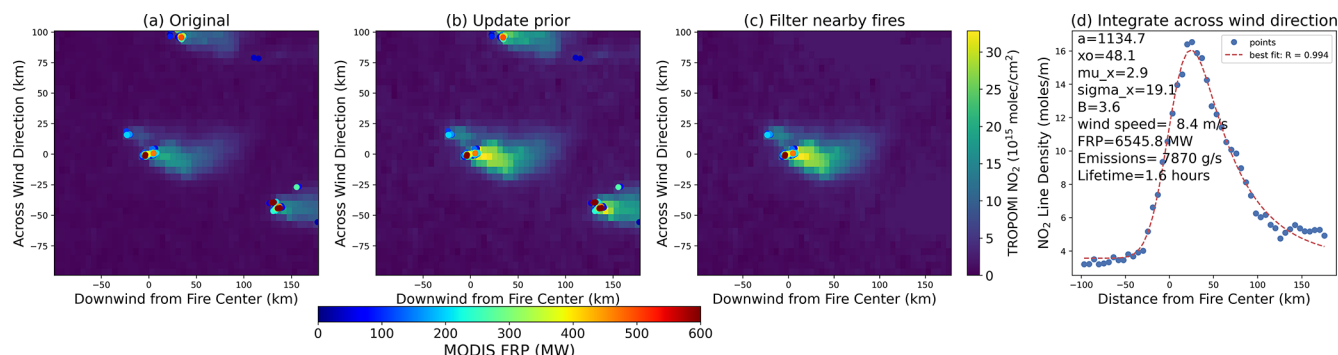

Figure 2. An example fire event illustrating four steps to estimate NO_x emissions and lifetime using the EMG approach: **(a)** original TROPOMI-retrieved NO₂ tropospheric vertical column density rotated to align with the wind direction; **(b)** retrieved NO₂ column density after replacing the a priori vertical profile of NO₂ from NASA GEOS-CF simulation; **(c)** central fire plume after filtering the nearby fire plumes; and **(d)** NO₂ line density calculated by integrating NO₂ column density across the wind direction. The red line in panel **(d)** shows the fitted line density using the EMG function (Eq. 7). The lifetime is estimated from Eq. (8), and the total NO_x emissions are estimated using Eq. (9). FRP is calculated as the sum of the FRP of all fire pixels detected by MODIS shown in panel **(c)**.

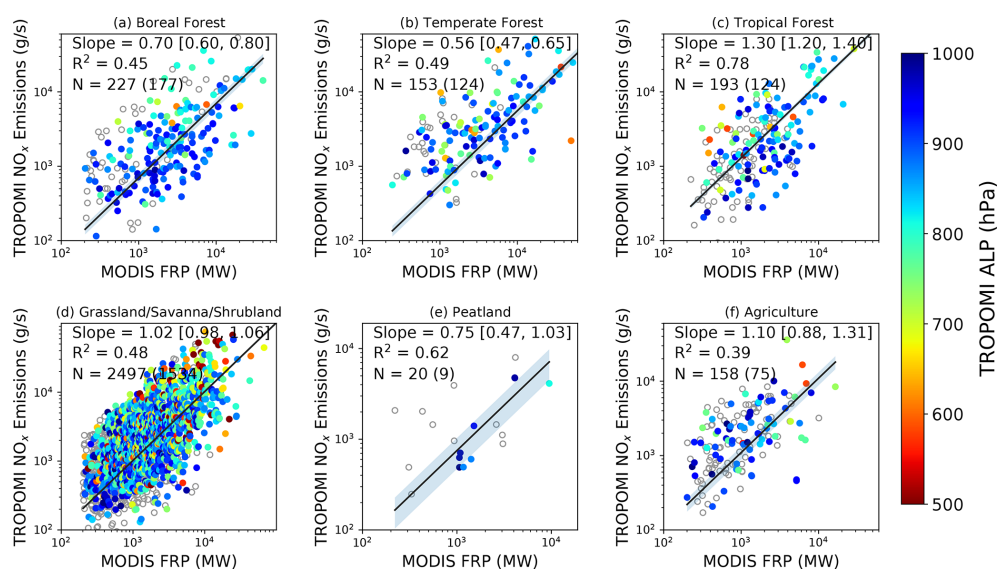

Figure 3. Scatter plots between TROPOMI-derived NO_x emissions (g s⁻¹) and MODIS FRP (MW) for six fuel types: **(a)** boreal forest; **(b)** temperate forest; **(c)** tropical forest; **(d)** herbaceous fuel type that combines grassland, savanna, and shrubland together; **(e)** peatland; and **(f)** agricultural fires. The colors represent the TROPOMI ALP of the corresponding fire events. Fire events without valid ALP are shown as black circles. The black line indicates the regression line estimated from ordinary least squares with the intercept fixed at zero. The shadow represents the 95 % CI of the fitted line, calculated based on the Student's *t*-distribution test. *R*² is the coefficient of determination of the linear fit. *N* is the number of fire events, and the number of fires with valid TROPOMI ALH is in the parenthesis. Emissions and FRP are on log scales.

imate the biomass burned consumption in top-down emission inventories such as Global Fire Assimilation System (GFAS; Kaiser et al., 2012). We define the emission coefficient (EC) as the mass of pollutant emitted per unit of radiative energy (i.e., emissions per FRP), which has been used to derive the emissions of chemical species from fires (Ichoku and Kaufman, 2005; Mebust et al., 2011; Mebust and Cohen, 2014). Figure 3 shows the relationship between TROPOMI-derived NO_x emissions with MODIS FRP for six different fuel types.

Overall, we find TROPOMI-derived fire NO_x emissions are positively correlated with MODIS FRP. We assess an overall EC by fitting a line with intercept fixed at zero. FRP explains 39 % to 78 % variance in emissions with the highest *R*² for tropical forest fires and lowest for agricultural fires. The variability not accounted for may be related to the uncertainty of satellite retrieval of NO₂, errors with the EMG approach, uncertainties with FRP (see Sect. 5), and/or true differences in NO_x ECs for different fires in similar ecosystems.

Figure 4. Comparison of the TROPOMI-derived NO_x emission factors with previous studies and those used in global biomass burning emission inventories. We include two estimates of NO_x emission factors: one using the original TROPOMI NO₂ (purple) and the other with updated a priori profile for AMF calculation (black). The error bars of TROPOMI NO_x EFs represent 95 % CI calculated based on Student's *t*-distribution test. The red dots show the mean NO_x EFs reported in previous studies compiled by Andreae (2019), and the error bars represent the standard deviation. The error bars of Mebust and Cohen (2014) are calculated using nonparametric bootstrap resampling. The error bars of Lindaas et al. (2021) indicate the overall uncertainty of measurements.

We compute the uncertainty of EC as 95 % confidence interval (CI) of the fitted EC based on the Student's *t*-distribution test. Comparing different forest types, EC is largest for tropical forests (1.30 [1.20, 1.40] g MJ⁻¹), followed by boreal forests (0.70 [0.60, 0.80] g MJ⁻¹) and temperate forests (0.56 [0.47, 0.65] g MJ⁻¹). Aggregating all grassland, savanna, and shrubland fires as a single fuel type, we obtain an overall EC of 1.02 [0.98, 1.06] g MJ⁻¹. Separating the fires into individual fuel types based on MODIS land cover classification leads to slightly improved *R*² for savanna and grassland, but the derived EC is similar: 1.00 [0.93, 1.07] g MJ⁻¹ for grassland, 1.13 [1.06, 1.19] g MJ⁻¹ for savanna, and 0.89 [0.78, 1.01] g MJ⁻¹ for shrubland (Fig. S5). Only 20 fires are classified as peatland fires, and we find a relatively good correlation between NO_x emissions and FRP with *R*² = 0.62 and EC = 0.75 [0.47, 1.03] g MJ⁻¹. For agricultural fires, there is a large scatter between NO_x emissions and FRP with *R*² = 0.39, and the estimated EC is 1.10 [0.88, 1.31] g MJ⁻¹. Updating the a priori profile of NO₂ enhances the spatial gradient of NO₂ (Fig. 2b), allowing for better estimates of fire NO_x emissions. Indeed, we find that using TROPOMI standard products gives a weaker correlation between FRP and NO_x emissions, and the ECs decrease by 46 % on average (Fig. S6).

4.4 Comparison with previous studies

To compare with previous studies, we convert the ECs to emission factors (EFs), assuming a constant ratio of fuel consumption to FRP: *K_r* = 0.41 kg MJ⁻¹ (Vermote et al., 2009; Mebust et al., 2011; Mebust and Cohen, 2014). Figure 4 shows the TROPOMI-derived NO_x EFs and the as-

sociated uncertainties (95 % CI) compared to previous studies. We find that satellite-derived NO_x EFs (hereafter EF_{sat}) are largely consistent with the mean reported in the Andreae (2019, hereafter EF_{andreae}), which represent an up-to-date compilation of field and laboratory measurements over the last 2 decades. In most fuel types except for temperate forest, EF_{sat} are largely consistent with EF_{andreae} to within 30 % difference. Our derived NO_x EF_{sat} for tropical forest (3.17 g kg⁻¹) is nearly twice as large as that in the boreal forest (1.70 g kg⁻¹), consistent with Andreae (2019), which also shows larger NO_x EFs over the tropical forest (2.81 g kg⁻¹) than boreal forest (1.18 g kg⁻¹). However, for the temperate forest, the derived NO_x EF_{sat} (1.36 g kg⁻¹) is less than half of EF_{andreae} (3.02 g kg⁻¹). There is a large spread of NO_x EFs for the temperate forests in literature, ranging from 0.49 g kg⁻¹ (Liu et al., 2017) to 7.44 g kg⁻¹ (Yokelson et al., 2007). Our derived NO_x EF_{sat}, however, is close to the in situ estimates of NO_x EFs (1.56 g kg⁻¹) from the recent aircraft campaign (i.e., WE-CAN) over the western US during summer 2018 (Lindaas et al., 2021). In non-forest fuel types, we find the smallest NO_x EF_{sat} (1.83 g kg⁻¹) over peatland, followed by grassland (2.49 g kg⁻¹) and agriculture (2.68 g kg⁻¹), which are close to EF_{andreae}. Using the standard TROPOMI NO₂ products without updating the a priori profile, the derived NO_x EFs are 44 % to 66 % of EF_{sat} and 26 % to 68 % of EF_{andreae}. Assessment of TROPOMI NO₂ with in situ measurements also suggests TROPOMI NO₂ is biased low over polluted regions, and replacing the coarse-resolution a priori profile with fine-resolution simulations could largely reduce the low biases (Judd et al., 2020; Tack et al., 2021). Our derived NO_x EFs are nearly 3 times larger than a previous study based on OMI observations, which sug-

Figure 5. The mean and standard deviation of TROPOMI-derived NO_x lifetimes from fires at different emissions (color) and wind speeds. Fire episodes with less than 2 m s⁻¹ wind speed are not shown.

gest NO_x EFs are lower than 1 g kg⁻¹ in all fuel types (Mebust and Cohen, 2014). Besides the differences in satellite instruments and methods, the discrepancy is partially due to less accurate representation of biomass burning emissions in the a priori profile of NO₂ in Mebust and Cohen (2014). Using the standard TROPOMI NO₂ products without updating the a priori profile, the derived NO_x EFs are similar to those developed by Mebust and Cohen (2014) for boreal and temperate forest fires but still higher over other fuel types.

As the development of biomass burning emission inventories is done by separate groups with different approaches, NO_x EFs used in these inventories also differ. We compare our derived NO_x EFs with those used in four commonly used global biomass burning emission inventories (Fig. 4), including (1) Global Fire Emissions Database (GFED; van der Werf et al., 2017), (2) Fire Inventory from NCAR (FINN; Wiedinmyer et al., 2011), (3) GFAS (Kaiser et al., 2012), and (4) QFED (Darmanov and Silva, 2015). We find that satellite-derived EF_{sat} best agree with those used in FINN for forest and grassland in terms of absolute magnitude and variations among fuel types. GFED and FINN use smaller EFs over boreal (0.9 and 1.8 g kg⁻¹) and temperate (1.9 and 1.3 g kg⁻¹) forest than tropical forest (2.6 g kg⁻¹), which is contrary to GFAS and QFED that use higher NO_x EFs of 3.4 and 3.0 g kg⁻¹ for the boreal and temperate forest than that for tropical forest (2.3 and 1.6 g kg⁻¹, respectively). Our derived NO_x EF_{sat} for tropical forest fires is larger than those used in emission inventories. For grassland, our derived NO_x EF_{sat} of 2.49 g kg⁻¹ is closest to that used in FINN (2.8 g kg⁻¹) and GFAS (2.1 g kg⁻¹) and smaller than that used in GFED and QFED (3.9 g kg⁻¹). For peatland fires, both GFED and GFAS use EF of 1.0 g kg⁻¹, which is smaller than our estimated EF of 1.83 g kg⁻¹, but we acknowledge a large uncertainty in our derived EF for peatland given the small number of samples. For agricultural fires, our derived NO_x EF_{sat} (2.68 g kg⁻¹) is slightly higher than that used

in GFAS (2.3 g kg⁻¹) but smaller than that used in GFED (3.11 g kg⁻¹) and FINN (3.5 g kg⁻¹).

4.5 Satellite-derived NO_x lifetime and its driven factors

We find a large variation of NO_x lifetimes in fire plumes. Figure 5 shows the variation of mean NO_x lifetime as a function of NO_x emissions at different wind speeds. We find an overall negative relationship between NO_x lifetime and emissions: NO_x lifetime decreases from over 5 h for fires with emissions less than 500 g s⁻¹ to less than 2 h for fires higher than 5000 g s⁻¹ (Fig. 5). We find similar NO_x lifetime using original TROPOMI NO₂ data (Fig. S7), largely because the derived NO_x lifetime is determined by the shape of fire plumes that are not affected by the a priori data. The varying lifetime with emissions suggests that the assumption of constant lifetime used in previous studies leads to an overestimate in emissions for small fires and an underestimate of emissions for big fires. At low emission levels (< 2000 g s⁻¹), NO_x lifetime tends to decrease with increasing wind speed, which is due to the vertical and horizontal diffusion effects that dilute the concentration of NO_x and thus alters the rate of NO_x removal due to the feedback on OH and the rate of NO_x removal (Valin et al., 2013). However, as NO_x emissions further increase (> 2000 g s⁻¹), the chemical removal becomes fast compared to dilution, and NO_x lifetime no longer depends on wind speed (Fig. 5). We note that the EMG-derived NO_x emissions depend on both NO_x abundance and lifetime (Eq. 9), and thus the observed negative emission–lifetime relationship may partially reflect that emissions are estimated from derived NO_x lifetime. However, we find a similar negative relationship between NO_x lifetime and TROPOMI NO₂ column density near the fire center (Fig. S8), indicating that chemical feedback of NO_x is the primary driver of the derived NO_x lifetime.

The NO_x chemical lifetime, in theory, is determined by its loss to HNO₃ and RONO₂. We use the 1-D PECANS model to simulate NO_x evolution downwind fire plumes and

Figure 6. Isopleth showing the NO_x lifetime dependence on NO_x emissions versus $P(\text{HO}_x)$. We run the PECANS 1-D model with varying NO_x emissions and $P(\text{HO}_x)$. The lifetime is estimated by fitting the modeled NO_x concentration along the wind direction with the EMG function (Eqs. 7 and 8). We run the model at a constant wind speed of 5 m s^{-1} , and the VOC reactivity is set constant at 4.8 s^{-1} for both groups (RVOC and OVOC). The black stars show the TROPOMI-observed mean NO_x emissions and lifetimes at wind speeds between 4 to 6 m s^{-1} , where the $P(\text{HO}_x)$ value is estimated as the level that gives the closest NO_x lifetime as observations at given NO_x emissions. The dashed line represents the fitted regression line.

calculate a lifetime by fitting model simulated NO_x concentration with the EMG function (Eq. 7). Figure 6 shows the dependence of the EMG-fitted NO_x lifetime on NO_x emissions rate and $P(\text{HO}_x)$. At low NO_x emissions, the NO_x lifetime decreases rapidly with increasing NO_x emissions, while almost independent of $P(\text{HO}_x)$, indicating a NO_x-limited regime. At the NO_x-limited regime, increasing NO_x facilitates the conversion from HO₂ to OH and thus faster loss of NO_x through formation of HNO₃ (e.g., Valin et al., 2014; Romer et al., 2020). The loss of NO_x through formation of RONO₂ also increases with NO_x emissions (e.g., Romer et al., 2020). As NO_x emissions further increase, the NO_x lifetime shows a strong dependence on $P(\text{HO}_x)$, and the NO_x lifetime increases slightly with NO_x emissions, indicating a NO_x-saturated regime. In the NO_x-saturated regime, as the loss of NO_x through the formation of HNO₃ consumes both NO_x and OH, increasing NO_x leads to decreasing oxidative capacity and thus a longer NO_x lifetime. If the NO_x lifetime is driven entirely by changes in NO_x concentration, the derived NO_x lifetime should first decrease and then increase with NO_x emissions, which is not found from the observed lifetime–emission relationship. Therefore, we infer that it is likely that $P(\text{HO}_x)$ increases with fire intensity in fire plumes, which, combined with increasing NO_x abundances, leads to an overall decrease of NO_x lifetime with NO_x emissions. If we assume VOC reactivities and branching ratio α are fixed, we could use TROPOMI-retrieved NO_x emissions and lifetimes to infer an approximate level of $P(\text{HO}_x)$. Fig-

ure 6 labels the satellite-retrieved mean NO_x lifetime at a given emission level, as well as the corresponding $P(\text{HO}_x)$. To match the observed negative lifetime–emission relationship, $P(\text{HO}_x)$ should also increase by nearly a factor of 4 from $15 \times 10^6 \text{ molec. cm}^{-3}$ for fires with lifetime longer than 4 h to $60 \times 10^6 \text{ molec. cm}^{-3}$ for fires with lifetime smaller than 1 h. The increase in $P(\text{HO}_x)$ may be related to increasing emissions of HONO that generate OH. A recent study suggests that previously underestimated HONO emissions from fires are responsible for two-thirds of the HO_x production from fresh fire plumes (Theys et al., 2020). The changes of $P(\text{HO}_x)$, however, should be of secondary importance compared to NO_x emissions in driving the observed variations in NO_x lifetime, which can be evidenced from the slower rate of the increase in inferred $P(\text{HO}_x)$ and small changes of the NO_x lifetime at high NO_x emissions (Fig. 6).

In addition to NO_x emissions and $P(\text{HO}_x)$, VOC reactivity is the third factor that affects the fitted NO_x lifetime. At low NO_x emissions, increasing RVOC reactivity leads to a shorter NO_x lifetime, but its impacts become smaller and reverse with increasing NO_x emissions (Fig. 7a). At low NO_x emissions, increasing RVOC reactivity facilitates the loss of NO_x through the formation of RONO₂. At high NO_x emissions, as both RVOC and NO_x consumes OH, increasing VOC leads to a longer NO_x lifetime. The formation of PAN acts as a temporal reservoir of NO_x, which also affects the evolution of NO_x. The formation of PAN depends on the concentration of OVOCs, OH level and temperature. Figure 7b shows the dependence of EMG-fitted NO_x lifetime as a function of NO_x emission rate and the reactivity of PAN's immediate precursor (OVOC). We find that increasing PAN formation through increasing OVOC reactivity will lead to an overall increase in EMG-fitted NO_x lifetime. The impact of OVOC is especially evident at low levels of NO_x emissions (Fig. 7b). Without PAN formation, the fitted NO_x lifetime will be shorter than that derived from TROPOMI observations, suggesting that PAN formation plays a non-negligible role in determining the evolution of NO_x and also the effective lifetime of NO_x.

5 Discussions on uncertainties

5.1 Uncertainties of satellite-retrieved NO₂ columns

Satellite retrievals of NO₂ columns are subject to uncertainties with spectral fitting and uncertainties from the a priori NO₂ profile shape and scattering weights needed for calculating AMFs and stratospheric NO₂ columns. Boersma et al. (2018) suggest an overall uncertainty of 35 % to 45 % for single-pixel OMI NO₂ retrieval, which should be smaller for TROPOMI NO₂ given its improved signal-to-noise ratio (van Geffen et al., 2020; Verhoelst et al., 2021). Due to the sporadic nature of fires, there is no validation of TROPOMI NO₂ columns with fire NO_x with ground-based measure-

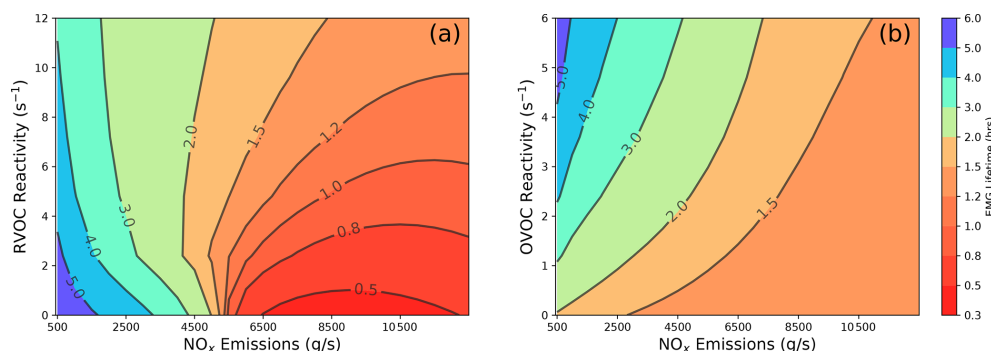

Figure 7. Same as Fig. 6 but showing the NO_x lifetime dependence on NO_x emissions versus the reactivities of (a) RVOC and (b) OVOC. We run the model at a constant wind speed of 5 m s⁻¹, and the $P(\text{HO}_x)$ is set constant at $50 \times 10^6 \text{ molec. cm}^{-3}$.

ments. Validation with ground-based differential optical absorption spectroscopy (DOAS) and Pandora measurements in urban stations show an overall good agreement between TROPOMI-retrieved and ground-based NO₂ columns, and an overall negative bias is reported, but the biases vary with stations (Lambert et al., 2020; Verhoelst et al., 2021).

Over polluted regions, the uncertainty and bias of single-pixel satellite retrieval of NO₂ columns is dominated by uncertainties of the AMF (Boersma et al., 2018). We replace the a priori profile shape of NO₂ using NASA GEOS-CF simulations that include daily biomass burning emissions, which leads to higher NO_x emission factors that are more consistent with in situ measurements. Bousseres (2014) similarly suggests that using a fire-specific NO₂ profile shape can lead to a near 60 % reduction in AMF. In the NASA GEOS-CF, 65 % biomass burning emissions are distributed within the boundary layer, which will lead to negative biases in AMF for large fires with plumes that rise well above the boundary layer. In our study, since the ALH is below 2000 m for the majority of fires, model uncertainties of the injection height should have small impacts on the retrieval of NO₂ columns. However, we notice that fire events with low ALP (< 700 hPa) tend to show higher NO_x emissions per FRP, and most outliers in Fig. 3 are associated with high aerosol layers. Since satellite instruments are more sensitive to NO₂ at higher altitudes, the inaccurate assumption of NO₂ concentrated within the boundary layer will lead to an underestimate of the AMF and thus an overestimate of the retrieved vertical NO₂ columns if the majority of NO₂ is injected into the free troposphere.

In addition, the large amounts of aerosols emitted from wildfires may also impact the retrieval of NO₂ columns from space. The impacts of aerosols depend on the magnitude, location, and optical properties (absorbing vs. scattering) of aerosols (Bousseres, 2014; Lin et al., 2015). In the TROPOMI NO₂ retrieval algorithm, the effects of aerosols are implicitly accounted for through modifying the cloud properties (Boersma et al., 2011). Bousseres (2014) suggest that an explicit correction is needed in the presence of clouds and scattering aerosols, and the effects of aerosol correction

can be as large as 100 % when cloud fraction is 30 % and AOD is higher than 1. In our study, the mean cloud fraction of the selected fire plumes is 9 %, and the mean AOD is 0.22, corresponding to a small uncertainty of less than 20 % based on Bousseres (2014).

5.2 Uncertainties of MODIS FRP

Since we derive NO_x EFs from the linear regression between TROPOMI NO_x emissions and MODIS FRP, uncertainties in MODIS FRP should also contribute to uncertainties of the satellite-derived NO_x EFs. Detection of MODIS FRP may be obscured by cloud, aerosols, or canopy cover. The uncertainty of FRP, however, is lower than 5 % for fires that aggregate 30 or more active fire pixels together (Freeborn et al., 2014). Our selected fire events are aggregated by 37 active fire pixels on average. To evaluate if our results are robust with the choice of FRP data, we conduct similar analysis with FRP measurements from Suomi NPP VIIRS sensors. In general, MODIS and VIIRS FRP are in good agreement ($R^2 = 0.72$, Fig. S9). VIIRS FRP is lower than MODIS FRP by 5.8 % on average. Deriving NO_x emission factors using VIIRS FRP, we find a slight increase of NO_x EFs for forest and agricultural fires but a decrease for peatland (Fig. S10). For herbaceous fires, where a large number of fires are sampled, the derived NO_x EF remains almost unchanged, suggesting that the difference in MODIS and VIIRS FRP should diminish as we increase the sample size. The overall relationship between NO_x emissions and FRP is similar for both VIIRS and MODIS, though stronger correlation is found for MODIS FRP. Overall, we estimate the difference in NO_x EFs using MODIS versus VIIRS FRP is ~ 2 %. Here we assume linear relationship between emission rate and FRP. While the validity of the relationship has been verified in laboratory (Wooster et al., 2005; Freeborn et al., 2008), field experiments (Wiggins et al., 2020), and satellite observations (Ichoku and Kaufman, 2005), the choice of the mass-to-energy conversion factor (K_T) slightly differs in Wooster et al. (2005, 0.368 g MJ^{-1}) and in Freeborn et

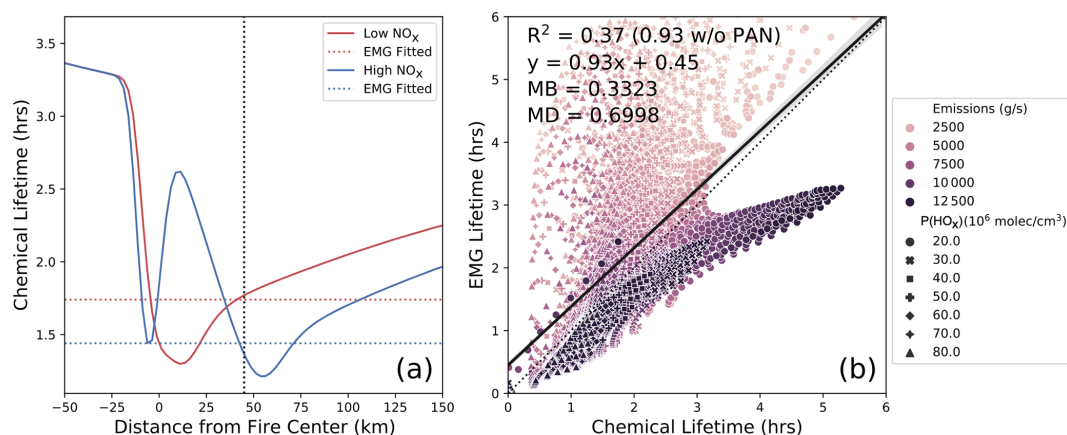

Figure 8. (a) Illustration of the variation of NO_x chemical lifetime with distance from fire center at both low (red) and high NO_x emissions (blue). The EMG-fitted effective lifetime is shown as horizontal dashed lines. The vertical line indicates the distance where chemical lifetime and EMG-fitted lifetime agree. (b) Scatter plot between EMG-fitted versus overall chemical NO_x lifetimes downwind calculated using varying NO_x emissions, $P(\text{HO}_x)$, and VOC reactivities, where the colors represent different emission levels, and the symbols represent different levels of $P(\text{HO}_x)$. The chemical lifetime is calculated as the mean NO_x concentration divided by the mean chemical loss of NO_x through the formation of HNO₃ and RONO₂ over downwind region. We define the regional mean as the region between fire center and the downwind area where NO_x concentration is higher than background, where background value is estimated from the EMG function (B in Eq. 7).

al. (2008, 0.453 g MJ⁻¹), suggesting an uncertainty of order 10 % for the value of K_r .

5.3 Uncertainties in the EMG approach

The first step of the EMG approach is to rotate TROPOMI observations along the wind direction. The derived NO_x lifetimes and emissions are therefore subject to uncertainties of the wind direction and speed due to uncertain plume heights that cross wind shear or the plume thermodynamics that are not captured by ERA5 wind data. In the case when the fire plume does not align with wind direction, calculating line density along the wind direction should lead to an underestimate of the e -folding distance. In this study, we only select fires with less than 30° rotation bias, and the mean rotation bias is 10°, which corresponds to less than 2 % underestimate of the e -folding distance. Uncertainty and variance of the wind speed, however, should lead to errors in the derived NO_x lifetimes. Here we determine the wind speed by interpolating the wind profile to TROPOMI-derived aerosol layer. Comparison of TROPOMI ALH with plume height from the Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) and the Multi-angle Imaging SpectroRadiometer (MISR) measurements suggest that TROPOMI ALH is overall 500 m lower (Griffin et al., 2020; Nanda et al., 2020). We estimate that an increase of 500 m ALH corresponds to ~ 22 % increase of the wind speed on average, meaning that NO_x lifetime will decrease by ~ 18 %.

Here we use the EMG approach to derive an effective NO_x lifetime of the entire fire plume. Chemical nonlinearities can result in an effective chemical lifetime that is averaged over

the plume where at each point in the plume evolution a different chemical lifetime occurs. Besides, the effective lifetime in practice will be confounded by the mixing such as those plume movement in different directions that reduces the line density. To assess if EMG-fitted effective NO_x lifetime is indicative of the chemical lifetime, we use the PECANS model to calculate an EMG-fitted lifetime and a chemical lifetime of NO_x from two permanent losses of NO_x through the formation of HNO₃ and RONO₂ over downwind region (i.e., mean NO_x concentration divided by the mean chemical loss of NO_x). The chemical lifetime of NO_x varies with location (Fig. 8a), which reaches a minimum near the source center at low NO_x emissions (NO_x-limited regime) but shows maximum at high NO_x emissions (NO_x-saturated regime). The effect of varying lifetime on the emission estimates is not considered with the EMG approach, which instead gives an overall effective NO_x lifetime of the plume. At low NO_x, the EMG-fitted lifetime is higher than the chemical lifetime at the fire center, but the reverse occurs at high NO_x (Fig. 8a). We notice that the EMG-fitted lifetime is overall more consistent with the chemical lifetime around 40 to 50 km downwind from the fire center, which should vary depending on the model input. Figure 8b compares the EMG-fitted lifetime with overall chemical lifetime over downwind regions under different NO_x emissions, $P(\text{HO}_x)$ and VOC reactivities. We find a moderate correlation between EMG-fitted lifetime and chemical lifetime ($R^2 = 0.37$). If PAN formation is not included, a nearly perfect correlation is found between the EMG-fitted and chemical lifetimes ($R^2 = 0.93$). In the lower troposphere, PAN is generally considered a sink of NO_x near the fire but a source of NO_x over downwind re-

gion, which deepens the gradient of NO₂ near the source but flattens the gradient downwind (Valin et al., 2013). For those large biomass burning events that inject PAN into upper troposphere, PAN acts as a stable reservoir of NO_x, leading to long-range transport of NO_x (Tereszczuk et al., 2013). The EMG approach is unable to capture the effects of PAN formation on the evolution of NO_x as it assumes NO_x decays exponentially. In the presence of PAN formation, we find the EMG approach tends to overestimate NO_x lifetime at low NO_x emission (< 5000 g s⁻¹), in which the flattening effect of PAN is more evident, while underestimating NO_x lifetime at high NO_x emissions and low $P(\text{HO}_x)$, in which the deepening effect of PAN takes over. Overall, we assess that the overestimate at low NO_x emissions (< 5000 g s⁻¹) causes around 33 % negative biases to the derived emissions and 18 % positive biases at high NO_x emissions (> 5000 g s⁻¹). In situ measurements show rapid formation of PAN in young smoke within 4 h of aging, and PAN contributes about 25 % of the total reactive nitrogen (Alvarado et al., 2010; Juncosa Calahorrano et al., 2021), suggesting a non-negligible role of PAN as a sink of NO_x near fire source.

6 Conclusions

We estimate NO_x emissions and lifetimes from over 3000 fires globally using daily TROPOMI retrievals of NO₂ tropospheric columns, and we derive NO_x emission factors by linking TROPOMI-derived NO_x emissions with MODIS FRP. The overall derived NO_x emission factors are 1.70, 1.36, and 3.17 g kg⁻¹ for the boreal, temperate, and tropical forest; 2.49 g kg⁻¹ for herbaceous (grassland, savannas, and shrubland combined) fires; 1.83 g kg⁻¹ for peatland; and 2.67 g kg⁻¹ for agricultural burning. Satellite-derived NO_x emission factors are largely consistent with the mean NO_x emission factors reported by previous field studies (Andreae, 2019). By studying a large number of fires globally, we provide more representative NO_x emission factors. These top-down emission estimates of NO_x could be used to assess biomass burning emission inventories in terms of both emission factors and fuel consumption, which could help diagnose the causes of discrepancies among different emission inventories.

Our study features three improvements over previous studies that use satellite measurements to derive NO_x emissions (Mebust et al., 2011; Mebust and Cohen, 2014; Schreier et al., 2015). First, we use observations from TROPOMI with finer spatial resolution and improved signal-to-noise ratio. Second, we relax the assumptions of constant NO_x lifetime by directly estimating lifetime through fitting the evolution of NO_x downwind with the EMG approach. Third, we replace the a priori profile of TROPOMI NO₂ retrieval with a high-resolution global model simulation from NASA GEOS-CF simulations to calculate AMF. This update results in steeper gradients between the plumes and the background and a more

accurate description of NO₂ vertical shape, reducing the discrepancy between satellite and in situ derived estimates of NO_x emission factors. The resolution of current global model simulation, however, is not sufficient to resolve the fine-scale chemical evolution of fire plumes, and better treatment of the fire injection is needed (Paugam et al., 2016). Assessment of the satellite retrieval uncertainty will benefit from high-resolution regional simulations combined with in situ measurements that sample individual fire smokes from the point of emission to downwind regions (Juncosa Calahorrano et al., 2021; Lindaas et al., 2020).

We observe decreasing NO_x lifetime with increasing fire NO_x emissions, which is indicative of NO_x-limited chemistry, where increasing NO_x emissions makes the chemical loss of NO_x more efficient. However, for the largest fires with high NO_x, a regime transition from a NO_x-limited regime to a NO_x-saturated regime is expected, where increasing NO_x emissions leads to a longer NO_x lifetime. Using a 1-D idealized plume model to interpret the factors affecting the NO_x lifetime, we infer that $P(\text{HO}_x)$ must also increase with fire intensity, consistent with observations that indicate a large source of HONO in fires (Theys et al., 2020; Peng et al., 2020). The formation of PAN also impacts the NO_x lifetime, but the evolution of NO_x due to the formation of PAN and its thermal decomposition over downwind areas is not well captured by the EMG approach that assumes exponential decay with NO_x downwind. Future studies will benefit from the integrative analysis of satellite retrievals of NO₂, HONO, and PAN to more completely describe the chemical evolution of reactive nitrogen from wildfires, thus allowing for better prediction of the air quality impacts of fires. TROPOMI is limited to a single overpass per day, which cannot resolve the short-term evolution of fire plumes observed by in situ measurements (e.g., Juncosa Calahorrano et al., 2021). The newly launched or upcoming geostationary satellite instruments such as GEMS and TEMPO will offer an unprecedented opportunity to continuously observe the emissions and chemical evolution of NO_x from fires that will no longer be limited to a single snapshot (Chance et al., 2013; Kim et al., 2019).

Code and data availability. The TROPOMI NO₂ data (<https://doi.org/10.5270/S5P-s4ljg54>, Copernicus Sentinel-5P, 2018a) and TROPOMI ALH (<https://doi.org/10.5270/S5P-j7aj4gr>, Copernicus Sentinel-5P, 2018b) are available from NASA Goddard Earth Sciences (GES) Data and Information Services Center (DISC, available at <https://disc.gsfc.nasa.gov/datasets/>, last access: 6 October 2021). MODIS (<https://doi.org/10.5067/FIRMS/MODIS/MCD14ML>, NASA FIRMS, 2018a) and VIIRS FRP (https://doi.org/10.5067/FIRMS/VIIRS/VNP14IMGT_NRT.002, NASA FIRMS, 2018b) data are available from NASA Earth Data Fire Information for Resource Management Systems, (available at <https://earthdata.nasa.gov/earth-observation-data/near-real-time/firms>, last access: 6 October 2021). MAIAC AOD

data are available from NASA's Land Processes Distributed Active Archive Center (LP DAAC) located at the USGS Earth Resources Observation and Science (EROS) Center (available at <https://doi.org/10.5067/MODIS/MCD19A2.006>, Lyapustin and Wang, 2018b). ERA5 hourly wind data are available from the Copernicus Climate Service (C3S) Climate Data Store (available at <https://doi.org/10.24381/cds.bd0915c6>, Hersbach et al., 2018). GEOS-CF simulations are available from NASA Global Modeling and Assimilation Office (available at https://gmao.gsfc.nasa.gov/weather_prediction/GEOS-CF/data_access/; NASA GMAO, 2020). PECANS code is available from <https://doi.org/10.5281/zenodo.3386652> (Laughner, 2019).

Supplement. The supplement related to this article is available online at: <https://doi.org/10.5194/acp-21-15569-2021-supplement>.

Author contributions. XJ and RCC conceived the project. QZ provided the PECANS code. XJ carried out the data analysis and prepared the article with contributions from all co-authors.

Competing interests. The contact author has declared that neither they nor their co-authors have any competing interests.
